The transient receptor potential channel C6 (TRPC6) is a slit diaphragm–associated protein in podocytes involved in regulating glomerular filter function. Gain-of-function mutations in TRPC6 cause hereditary focal segmental glomerulosclerosis (FSGS), and several human acquired proteinuric diseases show increased glomerular TRPC6 expression. Angiotensin II (AngII) is a key contributor to glomerular disease and may regulate TRPC6 expression in nonrenal cells. We demonstrate that AngII regulates TRPC6 mRNA and protein levels in cultured podocytes and that AngII infusion enhances glomerular TRPC6 expression in vivo. In animal models for human FSGS (doxorubicin nephropathy) and increased renin-angiotensin system activity (Ren2 transgenic rats), glomerular TRPC6 expression was increased in an AngII-dependent manner. TRPC6 expression correlated with glomerular damage markers and glomerulosclerosis. We show that the regulation of TRPC6 expression by AngII and doxorubicin requires TRPC6-mediated Ca2+ influx and the activation of the Ca2+-dependent protein phosphatase calcineurin and its substrate nuclear factor of activated T cells (NFAT). Accordingly, calcineurin inhibition by cyclosporine decreased TRPC6 expression and reduced proteinuria in doxorubicin nephropathy, whereas podocyte-specific inducible expression of a constitutively active NFAT mutant increased TRPC6 expression and induced severe proteinuria. Our findings demonstrate that the deleterious effects of AngII on podocytes and its pathogenic role in glomerular disease involve enhanced TRPC6 expression via a calcineurin/NFAT positive feedback signaling pathway. (Am J Pathol 2011, 179:1719–1732; DOI: 10.1016/j.ajpath.2011.06.033) The glomerular capillary filtration barrier consists of endothelial cells, glomerular basement membrane (GBM), and visceral epithelial cells or podocytes linked by the slit diaphragm. The slit diaphragm is a complex of interconnected proteins that connect podocyte foot processes, which provides both physical linkage and a signaling unit that regulates podocyte behavior.1 Damage to the glomerular capillary filter, in particular at the level of the podocyte and the slit diaphragm, is of crucial importance in the pathophysiology of proteinuria.1 Previously, the transient receptor potential channel C6 (TRPC6) has been identified as a novel slit diaphragm–associated pro-

tein in podocytes.\textsuperscript{2} Gain-of-function mutations in \textit{TRPC6} have been shown to cause autosomal dominant focal segmental glomerulosclerosis (FSGS), and enhanced podocyte expression of wild-type and mutant \textit{TRPC6} leads to glomerular damage.\textsuperscript{3–5}

TRPC channels are involved in several renal processes and diseases, ranging from tubular Ca\textsuperscript{2+} and Mg\textsuperscript{2+} reabsorption, through osmoregulation, to polycystic kidney disease.\textsuperscript{6–9} Podocytes express \textit{TRPC6}, and co-immunoprecipitation studies demonstrate that \textit{TRPC6} is associated with the slit diaphragm proteins nephrin and podocin, suggesting that \textit{TRPC6} is involved in signaling events at the slit diaphragm.\textsuperscript{2,10} The slit diaphragm complex is mechanically and functionally linked to the actin cytoskeleton. Cytoskeletal rearrangement has been suggested to underlie foot process effacement, which is a crucial early event in the pathophysiology of proteinuria.\textsuperscript{4} Several gain-of-function \textit{TRPC6} mutations have been identified in the \textit{TRPC6} encoding gene.\textsuperscript{2–4,11,12} In addition, glomerular \textit{TRPC6} expression is increased in acquired human proteinuric diseases, including nonfamilial FSGS and membranous glomerulopathy.\textsuperscript{4} Taken together, it is likely that enhanced Ca\textsuperscript{2+} influx due to an increased number of functional \textit{TRPC6} channels at the cell surface and/or enhanced channel activity compromises the structural integrity of the podocyte, leading to proteinuria.

\textit{TRPC6} is a receptor-operated cation channel, which can be activated by angiotensin II (AngII) through stimulation of the angiotensin type 1 receptor (AT1R) and secondary generation of diacylglycerol.\textsuperscript{3,13,14} AngII is a key contributor to the pathogenesis of glomerular disease, and the antiproteinuric effects of angiotensin-converting enzyme (ACE) inhibition and AT1R blockade are undisputed.\textsuperscript{15,16} In nonrenal cells, AngII activates \textit{TRPC6} currents and enhances \textit{TRPC6} transcription.\textsuperscript{14,17,18} In cardiomyocytes, AngII induces a \textit{TRPC6} and Ca\textsuperscript{2+}-dependent calcineurin/nuclear factor of activated T cells (NFAT) positive feedback loop, leading to increased \textit{TRPC6} transcription, driving cardiac hypertrophy.\textsuperscript{14,18} Podocytes also express both AT1R and AT2R, and AngII has detrimental effects in podocytes.\textsuperscript{15,16,19,20} AngII increases intracellular Ca\textsuperscript{2+} levels and induces changes in the actin cytoskeleton.\textsuperscript{21–23} When the AT1R is overexpressed in podocytes, transgenic rats develop podocyte damage and glomerulosclerosis.\textsuperscript{24} Furthermore, the overexpression of renin in mice induces podocyte damage and proteinuria, pathological effects that can be ameliorated by treating these transgenic animals with angiotensin receptor blockers (ARBs).\textsuperscript{25} In analogy to cardiomyocytes, AngII-induced Ca\textsuperscript{2+}-calcineurin-NFAT-mediated transcription of \textit{TRPC6} could also occur in podocytes; therefore, AngII could cause an up-regulation of \textit{TRPC6} expression, which results in elevated intracellular Ca\textsuperscript{2+} levels in podocytes in acquired proteinuric disease.

The aims of this study were to determine whether AngII regulates \textit{TRPC6} expression in podocytes, to gain insight into the downstream effectors of AngII/TRPC6-mediated signaling, and to evaluate its in vivo significance in experimental proteinuric glomerular disease.

### Materials and Methods

#### Animal Studies

Unilateral doxorubicin nephropathy was induced in rats by temporary clipping of the left renal artery and vein, followed by injection of 1.5 mg/kg of doxorubicin (Sigma-Aldrich, Zwijndrecht, the Netherlands) via the tail vein. After 12 minutes, when doxorubicin was cleared from the circulation, the clamp was removed. Bilateral doxorubicin nephropathy was induced by injection of 5 mg/kg of doxorubicin. Animals were treated with the ARB L158,809 (150 mg per liter of drinking water) from week 6 to 12 after induction of doxorubicin nephropathy. Additional animals received the ACE inhibitor (ACEi) lisinopril (75 mg per liter of drinking water) from week 6 to 18 after induction of doxorubicin nephropathy. Cyclosporine (20 mg/kg; dissolved in 0.5 mL of olive oil) or vehicle (0.5 mL of olive oil) was administered by daily oral gavage from week 4 to 6 after doxorubicin injection. For the AngII infusion studies, Wistar rats received a continuous AngII infusion (435 ng/kg/min) by subcutaneous osmotic minipumps during 3 weeks. Before termination, animals were housed in metabolic cages for 24 hours. Male homozygous TGR(mRen2)27 (Ren2 transgenic) rats and age-matched Sprague-Dawley rats were purchased from the Max Delbrück Center for Molecular Medicine (Berlin-Buch, Berlin, Germany). Wild-type and Ren2 transgenic rats were treated with a non-hypotensive dose of the ARB candesartan (0.05 mg/kg/d) with osmotic minipumps (Alzet model 2004) for 4 weeks. The animal ethics committees of the Radboud University Nijmegen and the University Medical Centre Groningen approved all animal studies.

#### Generation of Inducible Transgenic Mice

**Overexpressing Constitutive Active NFATc1 in Podocytes**

The transgenic TetO-HA-NFATc1\textsuperscript{\textit{nuc}} mouse line was generated in the laboratory of Dr. Gerald Crabtree and provided by Dr. Seung K. Kim (both from Stanford University, Stanford, California).\textsuperscript{26} In NFATc1\textsuperscript{\textit{nuc}}, the serine residues that are dephosphorylated by calcineurin are substituted with alanine residues, rendering it constitutively nuclear, constitutively active, and insensitive to nuclear kinases.\textsuperscript{27} These single transgenic mice were mated with podocin–reverse tetracycline-controlled transactivator (rtTA) mice to generate double transgenic doxycycline-inducible podocin-rtTA/TetO-HA-NFATc1\textsuperscript{\textit{nuc}} mice.\textsuperscript{28} Transgenic mice were genotyped using specific primer sets. Podocin-rtTA/TetO-HA-NFATc1\textsuperscript{\textit{nuc}} F1 littermates were mated to obtain F2 double transgenic mice for experimental procedures. Transgene expression was induced in podocytes by adding doxycycline (Sigma-Aldrich; 2 mg/mL in 7% sucrose, pH ~ 5) to the drinking water of 6- to 8-week-old double transgenic mice for 4 days. Simultaneously, the mice were fed a special diet chow containing doxycycline (2000 ppm). Control animals were either single transgenic mice that also received doxycycline or double transgenic mice that received no doxycycline.

Differentiated Conditionally immortalized mouse podocytes (MPC-5) were cultured as described previously.31 Glomerular expression of TRPC6 and other proteins was determined by semiquantitative scoring of immunofluorescence staining in 2-μm cryosections. We first verified our immunofluorescence method detecting TRPC6 expression in the passive Heymann nephritis rat model, in which enhanced glomerular TRPC6 expression was previously shown. TRPC6 was detected using two polyclonal antibodies directed against different epitopes in TRPC6 (Table 1): a rabbit polyclonal antibody against the C-terminal tail of rat TRPC6 and a rabbit polyclonal antibody directed against a conserved epitope in the N-terminal tail of mouse and rat TRPC6. Alexa-conjugated secondary antibodies were used subsequently. Both TRPC6 antibodies detected low levels of TRPC6 in the glomerulus of control animals, and TRPC6 expression was clearly increased in passive Heymann nephritis. Similar distribution patterns were observed using both anti-TRPC6 antibodies. When the primary antibody was omitted and only the secondary antibody was applied, no immunolabeling could be observed.

Glomerular TRPC6 expression was scored semiquantitatively from 0 to 5 based on the extent of TRPC6 immunofluorescence staining in the glomerulus (negative = 0, 1% to 20% positive = 1, 21% to 40% positive = 2, 41% to 60% positive = 3, 61% to 80% positive = 4, and 81% to 100% positive = 5). Semiquantification of other proteins was performed in a similar way. Scoring was performed independently by two investigators, who scored 35 to 50 glomeruli per animal on blinded sections. Focal glomerulosclerosis (FGS) was scored semiquantiatively on periodic acid–Schiff–stained paraffin sections in 50 glomeruli per kidney on a scale of 0 to 400. FGS lesions were defined as glomerular areas with mesangial expansion and adhesion formation simultaneously present in one segment.

### Cell Culture and Transfection

Conditionally immortalized mouse podocytes (MPC-5) were cultured as described previously.31 Differentiated podocytes were treated with doxorubicin (0.25 μg/mL) or puromycin aminonucleoside (PAN; 100 μg/mL) for 24 hours. Depending on the exact experimental setup, AngII (1 μmol/L), losartan (100 μmol/L), captopril (1 mmol/L), chymostatin (100 μmol/L), LaCl3 (50 μmol/L), 2-aminoethylidiphenylborane (2-APB) (10 μmol/L), and/or cyclosporine (cSA) (1 μmol/L) was added. A podocyte cell line stably expressing TRPC6 silencing short hairpin RNA (shRNA) was obtained after transfecting a TRPC6 shRNA construct with Lipofectamine 2000 into undifferentiated MPC-5 podocytes cultured at 33°C and subsequent selection in the presence of G418. Single clones were tested for TRPC6 mRNA and protein expression. Podocyte TRPC6 overexpression was achieved by lentiviral transduction of differentiated podocytes. FLAG-tagged wild-type mouse TRPC6 cDNA was cloned into the VVPW lentiviral expression vector (kind gift of G. Luca Gusella, New York, NY). Then 80% confluent HEK 293T cells were transfected in antibiotic-free Dulbecco’s modified Eagle’s medium, 10% fetal bovine serum with the VVPW plasmid, and the two helper plasmids psPAX2 and pCMV-VSVG (both from Addgene, Cambridge, MA) in a ratio of 3:2:1 using FuGENE, according to the manufacturer’s protocol. Control virus was produced using empty VVPW vector together with the same helper plasmids. After 16 hours, the medium was changed to Dulbecco’s modified Eagle’s medium and 10% fetal bovine serum, containing penicillin and streptomycin. At 24 and 48 hours thereafter, the virus-containing cell culture supernatant was harvested and stored at 4°C, the 24- and 48-hour collections were pooled and centrifuged (600 × g; 5 minutes), and the supernatant filtered through a 0.5 μm filter, aliquoted, and frozen at −80°C. Podocytes stably transfected with the pGL4.30 reporter plasmid expressing the luc2P firefly luciferase gene under the control of the NFAT response element (see below) were transduced with lentivirus 10 days after induction of differentiation in the presence of 4 μg/mL of hexadimethrine bromide for 16 hours, and NFAT activity was measured 4 days later.

### NFAT Reporter Assay

To assess NFAT activity in podocytes, a reporter podocyte cell line was generated that stably expresses the pGL4.30 reporter plasmid (Promega, Madison, WI).

Induction of NFATc1 nuc expression in isolated glomeruli was monitored by RT-PCR using DNase-treated total RNA and NFATc1 nuc specific primers.

**Immunohistochemistry**

Glomerular expression of TRPC6 and other proteins was determined by semiquantitative scoring of immunofluorescence staining in 2-μm cryosections. We first verified our immunofluorescence method detecting TRPC6 expression in the passive Heymann nephritis rat model, in which enhanced glomerular TRPC6 expression was previously shown. TRPC6 was detected using two polyclonal antibodies directed against different epitopes in TRPC6 (Table 1): a rabbit polyclonal antibody against the C-terminal tail of rat TRPC6 and a rabbit polyclonal antibody directed against a conserved epitope in the N-terminal tail of mouse and rat TRPC6. Alexa-conjugated secondary antibodies were used subsequently. Both TRPC6 antibodies detected low levels of TRPC6 in the glomerulus of control animals, and TRPC6 expression was clearly increased in passive Heymann nephritis. Similar distribution patterns were observed using both anti-TRPC6 antibodies. When the primary antibody was omitted and only the secondary antibody was applied, no immunolabeling could be observed.

Glomerular TRPC6 expression was scored semiquantitatively from 0 to 5 based on the extent of TRPC6 immunofluorescence staining in the glomerulus (negative = 0, 1% to 20% positive = 1, 21% to 40% positive = 2, 41% to 60% positive = 3, 61% to 80% positive = 4, and 81% to 100% positive = 5). Semiquantification of other proteins was performed in a similar way. Scoring was performed independently by two investigators, who scored 35 to 50 glomeruli per animal on blinded sections. Focal glomerulosclerosis (FGS) was scored semiquantiatively on periodic acid–Schiff–stained paraffin sections in 50 glomeruli per kidney on a scale of 0 to 400. FGS lesions were defined as glomerular areas with mesangial expansion and adhesion formation simultaneously present in one segment.

**Cell Culture and Transfection**

Conditionally immortalized mouse podocytes (MPC-5) were cultured as described previously.31 Differentiated podocytes were treated with doxorubicin (0.25 μg/mL) or puromycin aminonucleoside (PAN; 100 μg/mL) for 24 hours. Depending on the exact experimental setup, AngII (1 μmol/L), losartan (100 μmol/L), captopril (1 mmol/L), chymostatin (100 μmol/L), LaCl3 (50 μmol/L), 2-aminoethylidiphenylborane (2-APB) (10 μmol/L), and/or cyclosporine (cSA) (1 μmol/L) was added. A podocyte cell line stably expressing TRPC6 silencing short hairpin RNA (shRNA) was obtained after transfecting a TRPC6 shRNA construct with Lipofectamine 2000 into undifferentiated MPC-5 podocytes cultured at 33°C and subsequent selection in the presence of G418. Single clones were tested for TRPC6 mRNA and protein expression. Podocyte TRPC6 overexpression was achieved by lentiviral transduction of differentiated podocytes. FLAG-tagged wild-type mouse TRPC6 cDNA was cloned into the VVPW lentiviral expression vector (kind gift of G. Luca Gusella, New York, NY). Then 80% confluent HEK 293T cells were transfected in antibiotic-free Dulbecco’s modified Eagle’s medium, 10% fetal bovine serum with the VVPW plasmid, and the two helper plasmids psPAX2 and pCMV-VSVG (both from Addgene, Cambridge, MA) in a ratio of 3:2:1 using FuGENE, according to the manufacturer’s protocol. Control virus was produced using empty VVPW vector together with the same helper plasmids. After 16 hours, the medium was changed to Dulbecco’s modified Eagle’s medium and 10% fetal bovine serum, containing penicillin and streptomycin. At 24 and 48 hours thereafter, the virus-containing cell culture supernatant was harvested and stored at 4°C, the 24- and 48-hour collections were pooled and centrifuged (600 × g; 5 minutes), and the supernatant filtered through a 0.5 μm filter, aliquoted, and frozen at −80°C. Podocytes stably transfected with the pGL4.30 reporter plasmid expressing the luc2P firefly luciferase gene under the control of the NFAT response element (see below) were transduced with lentivirus 10 days after induction of differentiation in the presence of 4 μg/mL of hexadimethrine bromide for 16 hours, and NFAT activity was measured 4 days later.

**NFAT Reporter Assay**

To assess NFAT activity in podocytes, a reporter podocyte cell line was generated that stably expresses the pGL4.30 reporter plasmid (Promega, Madison, WI).
pGL4.30 includes the luc2P firefly luciferase gene under the control of the NFAT response element. Stably transfected clones were selected in the presence of hygromycin (300 µg/mL). Cells were differentiated for 10 days before lentiviral transduction and for 14 days before drug treatment. Stable cell lines were probed with Bright-Glo Luciferase Assay System (Promega), and luminescence was measured on a SpectraMax L luminescence microplate reader (Molecular Devices, Sunnyvale, CA).

To assess NFAT activity in TRPC6 knockdown cells, undifferentiated wild-type and TRPC6 stable knockdown podocytes were transiently transfected with the pGL4.30 reporter plasmid-expressing the luc2P firefly luciferase gene under the control of the NFAT response element and the pGL4.74 plasmid-expressing hRluc Renilla luciferase as an internal control to correct for transfection efficiency (Promega). Transiently transfected cells were assayed with Dual-Glo Luciferase Assay System (Promega).

Real-Time Quantitative RT-PCR Analysis
Total RNA was isolated from cultured podocytes and RNA was reverse transcribed (Transcriptor Kit; Roche Diagnostics, Mannheim, Germany). Real-time quantitative PCR was performed using SYBR Green Supermix (Roche Diagnostics) on a MyiQ Real-Time PCR Detection System (Bio-Rad Laboratories, Hercules, CA). TRPC6 expression was quantified by the delta-delta Ct method using glyceraldehyde 3-phosphate dehydrogenase (GAPDH) as the housekeeping gene. Sample sizes of 5 to 8 separate mouse podocyte cultures were used per experimental condition per experiment. Results were confirmed in at least two distinct experiments.

Immunocytochemistry
Podocytes grown on collagen A–coated plastic SlideFlasks (NUNC, Roskilde, Denmark) were fixed and incubated with a rabbit polyclonal anti-mouse TRPC6 antibody (Table 1). Alexa-conjugated secondary antibodies were applied, cells were embedded, and images were collected as described above.

Immunoblotting
Podocytes or isolated glomeruli were lysed in a 20 mmol/L Tris pH 8 buffer containing 500 mmol/L NaCl, 0.5% (wt/vol) 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS), 1% (vol/vol) Triton X-100, 2 pg of pepstatin, and the Complete Mini cocktail of protease inhibitors (Roche Diagnostics). Protein concentration was determined and samples containing equal amounts of protein were resolved on a 10% (wt/vol) SDS-PAGE gel and blotted to polyvinylidene difluoride membranes (Bio-Rad Laboratories). Blots were incubated with rabbit polyclonal anti-mouse TRPC6 antibody, mouse anti-β-actin antibody, or mouse anti-GAPDH antibody (Table 1) and subsequently with peroxidase-labeled secondary antibodies. Proteins were visualized using chemiluminescence, and signal intensity was determined digitally.

Ca2+ Imaging Studies
Imaging of intracellular Ca2+ concentration ([Ca2+]i) with Fura-2 was performed in selected populations of cells with an inverted fluorescence microscope setup. In brief, conditionally immortalized mouse podocytes expressing either a control shRNA or TRPC6 shRNA construct were incubated with 5 µmol/L Fura-2-AM (Sigma-Aldrich) for 45 minutes at room temperature. Cells were treated with 100 µmol/L 1-oleoyl-2-acetylsn-glycerolin (OAG) in the presence or absence of 2-APB, and [Ca2+]i, was measured. After stimulation, the extracellular buffer was exchanged with 2 mmol/L Ca2+ to distinguish membrane-associated channel-dependent changes in [Ca2+]i. Fluorescence data are presented as a 340/380-nm ratio. Data from selected cell populations were averaged, and statistical analysis was performed on multiple experiments.

Statistical Analysis
Data are expressed as mean ± SEM. Statistical comparisons were analyzed by one-way analysis of variance and Fisher’s multiple comparison. P < 0.05 was considered significant.

Results
Glomerular TRPC6 Expression Correlates with Podocyte Injury in Doxorubicin Nephropathy
Unilateral doxorubicin nephropathy was induced and resulted in a significant proteinuria (161 ± 52 mg/24 h, 246 ± 14 mg/24 h, and 388 ± 28 mg/24 h at 6, 18, and 30 weeks, respectively, after doxorubicin injection). Glomerular TRPC6 protein expression was increased in doxorubicin-exposed kidneys when compared with control kidneys (Figure 1, A and B). TRPC6 expression and proteinuria increased over time (Figure 1B), and proteinuria tended to increase with higher TRPC6 protein levels (r2 = 0.8028; P = 0.0001) (Figure 1C). FGS as a direct measure of glomerular injury was significantly increased in doxorubicin-exposed kidneys (8 ± 3 versus 1 ± 1 at 6 weeks, 47 ± 11 versus 12 ± 4 at 18 weeks, and 89 ± 24 versus 33 ± 7 at 30 weeks). The FGS score correlated with TRPC6 protein levels (r2 = 0.8028; P < 0.0001) (Figure 1D). TRPC6 expression was also enhanced in bilateral doxorubicin nephropathy (Figure 1E), as were cortical TRPC6 mRNA levels (Figure 1F), suggesting that doxorubicin nephropathy alters transcription of TRPC6. In glomeruli from doxorubicin nephropathy rats, TRPC6 co-localized with desmin, which is a marker for injured podocytes, whereas in control kidneys desmin and TRPC6 expression levels were low (Figure 1G). No co-localization was found for TRPC6 and glomerular α-smooth muscle actin (α-SMA), which
is a mesangial injury marker (Figure 1H). However, α-SMA and TRPC6 were expressed in similar glomerular segments in doxorubicin nephropathy, whereas α-SMA expression was negative in control kidneys. Because controls show, as expected, no α-SMA expression and low TRPC6 expression, we included co-staining of synaptopodin with α-SMA instead as a control. To further study the relationship between glomerular damage and TRPC6 expression, we performed co-stainings of TRPC6 with the heparan sulfate (HS) antibody JM403, which recognizes N-unsubstituted HS moieties present in the GBM. Immunostaining for HS in the GBM was linear in control animals, but in glomerular areas with high TRPC6 expression in doxorubicin nephropathy, HS staining was reduced and aberrantly distributed (Figure 1I).

**Figure 1.** Glomerular TRPC6 expression in the doxorubicin nephropathy (DN) rat model. Representative images of glomerular immunolabeling for TRPC6 in control rats (CTR) and rats with DN (A). TRPC6 expression was determined by semiquantitative analyses of immunofluorescence signals in doxorubicin (DOXO)–exposed and contralateral control (CTR) kidneys, 6, 18, and 30 weeks after treatment (B). Correlation between glomerular TRPC6 expression in the DOXO-exposed kidney and proteinuria in the unilateral DN model (C). Correlation between semiquantitative scoring for TRPC6 protein level and the FGS score in DOXO-exposed (closed dots) and contralateral control (open dot) kidneys (D). TRPC6 protein (E) and mRNA levels (F) in bilateral DN. Co-localization studies for TRPC6 with the marker for injured podocytes desmin (G), the mesangial injury marker α-SMA (H), or HS in the GBM (I). *P < 0.05.

**ARBs Prevent the Increase of TRPC6 Expression During Podocyte Injury in Vivo and in Vitro**

Because of the proposed role for AngII in doxorubicin-induced glomerular injury, we evaluated the effect of ARBs on TRPC6 expression in glomeruli. When rats with bilateral doxorubicin nephropathy were treated with an ARB, glomerular TRPC6 levels were reversed to levels of untreated control animals (Figure 2, A and B). Doxorubicin exposure did not alter blood pressure, whereas ARB treatment significantly reduced blood pressure (Figure 2C) and ameliorated proteinuria (245 ± 43 mg/24 h versus 697 ± 94 mg/24 h). ARBs reduced glomerular injury as indicated by the FGS score.
score (Figure 2D), as well as glomerular desmin (Figure 2E) and α-SMA protein levels (Figure 2F). We also studied TRPC6 expression in PAN- and doxorubicin-induced podocyte injury in vitro. Enhanced TRPC6 expression has been previously demonstrated in PAN-treated cultures podocytes. Indeed, PAN treatment of immortalized mouse podocytes significantly increased TRPC6 mRNA levels, which was ameliorated by co-incubation with the ARB losartan (Figure 3A). In addition to the evaluation of glomerular TRPC6 levels in the in vivo doxorubicin nephropathy rat model, we also studied TRPC6 expression in doxorubicin-treated podocytes in vitro. Doxorubicin also increased TRPC6 mRNA levels in cultured podocytes, which was partially prevented by ARB co-incubation (Figure 3B). To ascertain whether these transcriptional changes resulted in alterations of TRPC6 protein levels, we performed immunocytochemistry (Figure 3C) and immunoblot analyses (Figure 3D). Quantitative analyses of immunoblots showed that doxorubicin increased TRPC6 protein expression in podocytes, which was inhibited by ARB co-incubation (Figure 3E). Furthermore, ARB preincubation in addition to co-incubation completely prevented the doxorubicin-induced TRPC6 up-regulation (Figure 3F).

**Elevated AngII Levels Increase TRPC6 Expression in Vitro and in Vivo**

Because the data described above suggest that AngII could be an important mediator of TRPC6 expression in the podocyte, we evaluated whether in vivo and in vitro AngII application affected TRPC6 expression. When rats were infused with AngII during 21 days, semiquantitative immunohistochemistry demonstrated significantly enhanced glomerular TRPC6 expression (Figure 4A), accompanied by a mild proteinuria (110 ± 27 mg/24 h versus 15 ± 1 mg/24 h in controls). Similarly, when podocytes were cultured in the presence of AngII, TRPC6 mRNA levels were increased (Figure 4B). Subsequently, we studied glomerular TRPC6 expression in Ren2 transgenic rats, an animal model for AngII-mediated glomerular and tubulo-interstitial injury. Glomerular TRPC6 expression was significantly increased in Ren2 transgenic rats, whereas treatment with the ARB
protein levels were normalized to

levels \((P < 0.05)\). Effect of preincubation with ARB 1 hour before DOXO application (ARB) \((P < 0.05)\). To study the Ca\(^{2+}\) influx dependency of this mechanism, cyclosporine also through TRPC6 itself induces NFAT-mediated TRPC6 expression (Figure 5E). In cardiomyocytes, Ca\(^{2+}\) influx through TRPC6 itself induces NFAT-mediated TRPC6 transcription.\(^{14}\) We demonstrate that in the podocyte, enhancing TRPC6 expression through lentiviral infection with a TRPC6-FLAG construct (Figure 5F) resulted in enhanced NFAT activation (Figure 5G). In line with our hypothesis, cyclosporine administration blocked the NFAT activation secondary to exogenous TRPC6 overexpression (Figure 5G). Substantiating the \textit{in vivo} significance of these \textit{in vitro} findings, cyclosporine also significantly decreased doxorubicin-induced glomerular TRPC6 expression (Figure 5H) and albuminuria in rats \((178 \pm 58 \text{ mg/24 h} \text{ versus } 311 \pm 46 \text{ mg/24 h})\).

To study the Ca\(^{2+}\) influx dependency of this mechanism, we demonstrated that when doxorubicin-challenged podocytes were treated with LaCl\(_3\), which is a general blocker of Ca\(^{2+}\) influx across cell membranes, TRPC6 mRNA levels were significantly decreased (Figure 6A). Furthermore, the TRPC channel blocker 2-APB inhibited doxorubicin—

doxorubicin nephropathy. The ACEi lisinopril significantly decreased glomerular TRPC6 expression (Figure 4E). ACEi also decreased blood pressure (Figure 4F), proteinuria \((289 \pm 77 \text{ mg/24 h} \text{ vs } 641 \pm 91 \text{ mg/24 h})\), and the FGS score (Figure 4G). Podocytes also harbor a local renin-angiotensin-aldosterone system (RAAS), whose components are synthesized on podocyte injury.\(^{34,35}\) However, high concentrations of the ACEi captopril and/or chymostatin, an inhibitor of non—ACE-mediated AngII production, did not affect doxorubicin-induced TRPC6 expression in cultured podocytes (Figure 4H), suggesting that injury-induced AngII production by the podocyte itself is not involved.

**AngII and Doxorubicin-Induced Increase of TRPC6 Expression Involves Calcineurin/NFAT Signaling**

Next we evaluated whether the downstream signaling events of AngII-induced AT1R activation in podocytes involve the Ca\(^{2+}\)-dependent calcineurin/NFAT pathway, as it does in other cell types.\(^{14,18}\) We demonstrated that calcineurin inhibition through application of cyclosporine prevented both doxorubicin- (Figure 5A) and AngII-induced (Figure 5B) TRPC6 expression. In other cell types it is well established that activated calcineurin dephosphorylates the transcription factor NFAT, thereby enhancing transcription of NFAT-responsive genes, including TRPC6.\(^{14,36}\) To analyze NFAT activity in podocytes, we used a reporter system driving luciferase expression under the control of an NFAT-responsive element. PAN administration, which increased TRPC6 expression, enhanced NFAT activation, whereas this effect was attenuated by the calcineurin inhibitors cyclosporine and tacrolimus (Figure 5C). Similarly, doxorubicin administration significantly enhanced NFAT activation, whereas cyclosporine or ARB treatment attenuated the doxorubicin-induced NFAT-controlled luciferase expression (Figure 5D). AngII treatment also enhanced NFAT-controlled luciferase expression in podocytes, and, again, both cyclosporine and ARB treatment were able to block this effect (Figure 5E). In cardiomyocytes, Ca\(^{2+}\) influx through TRPC6 itself induces NFAT-mediated TRPC6 transcription.\(^{14}\) We demonstrate that in the podocyte, enhancing TRPC6 expression through lentiviral infection with a TRPC6-FLAG construct (Figure 5F) resulted in enhanced NFAT activation (Figure 5G). In line with our hypothesis, cyclosporine administration blocked the NFAT activation secondary to exogenous TRPC6 overexpression (Figure 5G). Substantiating the \textit{in vivo} significance of these \textit{in vitro} findings, cyclosporine also significantly decreased doxorubicin-induced glomerular TRPC6 expression (Figure 5H) and albuminuria in rats \((178 \pm 58 \text{ mg/24 h} \text{ versus } 311 \pm 46 \text{ mg/24 h})\).

To study the Ca\(^{2+}\) influx dependency of this mechanism, we demonstrated that when doxorubicin-challenged podocytes were treated with LaCl\(_3\), which is a general blocker of Ca\(^{2+}\) influx across cell membranes, TRPC6 mRNA levels were significantly decreased (Figure 6A). Furthermore, the TRPC channel blocker 2-APB inhibited doxorubicin—

and AngII-induced TRPC6 expression (Figure 6C). Because there are no TRPC6-specific blockers available to date, we used a TRPC6 knockdown technique using TRPC6 shRNA (Figure 6D) to evaluate the effect of reduced TRPC6 expression levels on AngII-induced NFAT activation. Indeed, TRPC6 knockdown decreased AngII-induced NFAT activation in podocytes compared with control cells (Figure 6E). This indicated that TRPC6, at least in part, mediates the effect of AngII on NFAT activation. To confirm that the TRPC channel blocker 2-APB and the TRPC6 knockdown approach indeed affected receptor-mediated Ca\(^{2+}\) influx, we evaluated Fura-2 ratiometry secondary to stimulation by the diacylglycerol analog OAG in podocytes. Indeed, TRPC6 knockdown in podocytes resulted in reduced OAG-stimulated Ca\(^{2+}\) influx compared with nontransfected podocytes or cells transfected with control shRNA (Figure 6F). Furthermore, 2-APB application significantly reduced OAG-stimulated Ca\(^{2+}\) influx (Figure 6F). Importantly, 2-APB did so in untransfected podocytes and cells transfected with control shRNA but to a much lesser degree in the TRPC6 knockdown situation (Figure 6G), strongly suggesting that TRPC6 is the major TRPC channel mediating the 2-APB-sensitive Ca\(^{2+}\) influx in cultured podocytes.

Podocyte-Specific Overexpression of Activated NFAT in Mice Increases TRPC6 Expression and Induces Proteinuria

Our findings suggest that in podocytes TRPC6-mediated activation of NFAT enhances TRPC6 transcription and is eventually detrimental to the glomerular filter, causing proteinuria. Because doxorubicin and AngII, two inducers of podocyte damage and proteinuria in animal models, activate this pathway and TRPC6 gain-of-function mutations and overexpression underlie human glomerular disease, it is possible that NFAT activation per se induces podocyte damage. To test this hypothesis, we...
induced overexpression of a constitutively active NFATc1 variant (NFATc1\textsuperscript{\textsubscript{nuc}}) in podocytes of adult transgenic mice. In NFATc1\textsuperscript{\textsubscript{nuc}}, the serine residues that are dephosphorylated by calcineurin are mutated to alanines, rendering this NFATc1 mutant form constitutively nuclear and insensitive to nuclear kinases.\textsuperscript{27} We crossed an inducible transgenic mouse line expressing NFATc1\textsuperscript{\textsubscript{nuc}} under the control of a tetracycline-responsive element with podocin-rtTA mice, which express the rtTA, specifically in podocytes.\textsuperscript{26,28} The resulting double transgenic offspring expressing the NFATc1\textsuperscript{\textsubscript{nuc}} transgene developed significant proteinuria (Figure 7, B and C) and showed significantly elevated TRPC6 protein levels in isolated glomeruli when compared with control animals (Figure 7, D and E). This experiment shows that NFAT activation in podocytes per se is sufficient to induce proteinuria in mice and that NFAT regulates TRPC6 expression in podocytes in vivo.

Discussion

In the present study we demonstrate that a deleterious positive feedback mechanism, in which TRPC6-mediated Ca\textsuperscript{2+} influx stimulates NFAT-dependent TRPC6 expression, is involved in AngII-associated podocyte injury. We show in different in vitro and in vivo models that AngII, a key contributor to the pathogenesis of glomerular dis-
ease, increases TRPC6 expression in podocytes. Glomerular TRPC6 expression was up-regulated by AngII infusion and in the Ren2 transgenic rat model for AngII-associated renal damage, an effect that was ameliorated by ARB treatment. TRPC6 expression was also enhanced in the doxorubicin nephropathy model for acquired progressive glomerular damage and proteinuric disease and positively correlated with markers for podocyte and glomerular damage. Blocking the effect of AngII in doxorubicin-induced in vitro podocyte injury and in vivo glomerular disease down-regulated TRPC6 expression and ameliorated glomerular damage and proteinuria. Thus, doxorubicin-induced TRPC6 expression in podocytes is mediated through AngII/AT1R signaling. Doxorubicin-induced and AngII-mediated TRPC6 transcription appears to be controlled by the Ca\(^{2+}\)-dependent calcineurin/NFAT pathway, involving Ca\(^{2+}\) influx through TRPC6 itself. Indeed, we demonstrate in a novel transgenic mouse model that podocyte-specific NFAT activation induces glomerular TRPC6 expression and severe proteinuria.

Doxorubicin induces glomerular injury in rats, giving rise to progressive proteinuria and loss of renal function. Glomerular TRPC6 expression was enhanced in the unilateral and bilateral doxorubicin nephropathy models for acquired glomerular disease. Because doxorubicin also increased TRPC6 mRNA and protein expression in cultured podocytes, we conclude that the increased TRPC6 expression is a direct result of doxorubicin acting on the podocyte. TRPC6 was detectable in healthy
control animals but maximally enhanced in segmental glomerular lesions in doxorubicin nephropathy. These glomerular segments showed evidence of injury, where TRPC6 co-localizes with desmin as a marker for podocyte injury. Accordingly, glomerular TRPC6 expression showed a significant correlation with the extent of glomerulosclerosis. Because highly sclerotic glomeruli lacked TRPC6 expression, this correlation may be lost with advanced FGS when podocyte depletion occurs. The pathological characteristics of long-term doxorubicin nephropathy, including segmental glomerulosclerosis, closely resemble those seen in human FSGS. Thus, increased TRPC6 expression appears crucially involved in the pathogenesis of podocyte and glomerular damage, leading to glomerulosclerosis and proteinuria in FSGS. These findings are in line with increased TRPC6 expression in human acquired FSGS and TRPC6 gain-of-function mutations leading to hereditary FSGS.

We demonstrate that AngII infusion enhances glomerular TRPC6 expression in rats and that AngII application directly regulates TRPC6 expression in podocytes. Furthermore, this study is the first to demonstrate that ARBs and ACEIs, counteracting the effects of AngII, decrease TRPC6 overexpression in experimental glomerular disease. Because TRPC6 expression is enhanced in acquired human glomerular disease, and in the absence of specific TRPC6 blockers for clinical use, our data suggest that treatment with ARBs and ACEIs are a potential way to reduce TRPC6 expression. ARBs and ACEIs are known to reduce glomerular injury, decrease proteinuria, and ameliorate renal function decline in chronic renal disease, which is partly independent of their antihypertensive action. We and others have previously shown that the RAAS is involved in doxorubicin nephropathy, and the key pathological involvement of AngII in glomerular disease is widely accepted. Accordingly, we now demonstrate that doxorubicin-induced TRPC6 expression in podocytes is AngII-mediated. In doxorubicin nephropathy, ACEIs down-regulated TRPC6 expression by its effect on the systemic but not the local podocyte RAAS. Furthermore, in the Ren2 transgenic model of AngII-mediated renal injury, TRPC6 levels were significantly enhanced, which appeared to be a direct effect of AngII exemplified by the partial normalization of its expression after short-term ARB treatment. Several lines of evidence support that AngII is injurious to podocytes. For example, transgenic rats overexpressing the AT1R on their podocytes show structural podocyte damage and proteinuria, progressing to FSGS. AngII infusion reduces nephrin expression and provokes podocyte injury in experimental glomerulopathies, which is inhibited by RAAS blockade. Interestingly, adverse effects of AngII-mediated stimulation of TRPC6 have also been shown in nonrenal cells. Stimulation of TRPC6 by AngII plays an important role in vascular smooth muscle cell contraction, and TRPC6 expression in pulmonary vascular smooth muscle cell is increased in idiopathic pulmonary arterial hypertension. Importantly, AngII-induced Ca influx through TRPC6 was shown to activate the calcineurin/NFAT signaling pathway and increase TRPC6 expression in cardiomyocytes, resulting in
cardiomyocyte hypertrophy. A recent study by Eckel et al showed that AngII-induced albuminuria was not prevented but was significantly ameliorated in TRPC6 knockout compared with wild-type mice. Altogether, this demonstrates that AngII-induced and calcineurin/NFAT-mediated TRPC6 expression in the podocyte is an important mediator in the pathogenesis of podocyte injury and glomerular disease.

Thus, we hypothesized that the Ca\(^{2+}\) influx-stimulated calcineurin/NFAT pathway is involved in downstream signaling activated by AngII in the podocyte (proposed model depicted in Figure 8). The inhibitor of TRPC channel activity 2-APB reduced receptor-mediated Ca\(^{2+}\) influx into cultured podocytes, as well as doxorubicin-induced and AngII-mediated TRPC6 up-regulation. This demonstrates that TRPC6 expression is Ca\(^{2+}\)-dependent and that Ca\(^{2+}\) influx through TRPC channels could be involved. It was previously shown that AngII induces elevation of [Ca\(^{2+}\)]\(_i\) in the podocyte by influx from the extracellular compartment, which can be blocked by ARBs. Among other downstream targets, Ca\(^{2+}\) influx activates the serine-threonine phosphatase calcineurin, which dephosphorylates the NFAT family of transcription factors, leading to the transcription of NFAT-responsive genes. We demonstrated that AngII activates NFAT in podocytes and that calcineurin inhibition and blocking of the AT1R inhibit doxorubicin-induced and AngII-mediated NFAT activation and TRPC6 expression. The TRPC6 promoter harbors two conserved NFAT-responsive sites, required for TRPC6 transcription in response to Ca\(^{2+}\)-dependent calcineurin/NFAT signaling in cardiomyocytes. Schloendorf et al have shown that introduction of a gain-of-function TRPC6 mutant in podocytes enhances NFAT activation in vitro. Furthermore, they reported that cyclosporine, without directly affecting TRPC6 channel activity, inhibits TRPC6-mediated NFAT signaling. Thus, Ca\(^{2+}\) influx through TRPC6 itself could play a role in an AT1R-stimulated calcineurin/NFAT signaling cascade. This hypothesis is supported by our data showing that lentiviral TRPC6 overexpression in podocytes activates NFAT in an AT1R- and calcineurin-dependent manner. Importantly, we also demonstrated that TRPC6 knockdown decreases Ca\(^{2+}\) influx and inhibits AngII-induced NFAT activation in podocytes. In line with these data, it was recently shown that in podocytes isolated from TRPC6 knockout and wild-type mice the response to AngII significantly differs, showing a reduced Ca\(^{2+}\) current in the TRPC6 knockout podocytes. In a similar TRPC6 shRNA approach, Greka and coworkers recently showed that down-regulation of TRPC6 reduces AngII-evoked Ca\(^{2+}\) transients in podocytes, along with effects on the podocyte cytoskeleton. The residual NFAT activation in our experiments might be related to remaining TRPC6 expression but could also mean that the cascade is not solely TRPC6 dependent and other (TRPC) Ca\(^{2+}\) channels or influx mechanisms are involved. Expression of other TRPC channels in the podocyte has been shown, and TRP channels form heterotetramers in which different TRP subunits combined form functional channels.

Altogether, our data are the first to demonstrate that AngII induces a calcineurin/NFAT pathway in podocytes that appears to be dependent on Ca\(^{2+}\) influx through TRPC6 and, in addition, leads to enhanced expression of TRPC6 itself, thus forming a potentially deleterious feedback loop. Zhang et al previously suggested that AngII-induced TRPC6 expression might involve MAPK, ERK, JNK, and NF-kB. In cardiomyocytes, those pathways
were also described, and receptor-activated TRPC6-mediated NFAT activation was shown to inhibit JNK and ERK. To demonstrate that NFAT activation in podocytes is independently capable of enhancing TRPC6 expression in vivo and inducing proteinuria, we generated a transgenic mouse model in which a constitutively active NFAT mutant could be induced in a podocyte-specific manner. As originally hypothesized, we demonstrated that induction of NFAT results in increased glomerular TRPC6 expression and the development of severe proteinuria. On submission of this work another article appeared that also describes the effect of NFAT overexpression and the subsequent development of proteinuria; however, the involvement of TRPC6 was not specifically studied in that article. Our data confirm that the activation of NFAT in podocytes is sufficient to induce proteinuria and substantiate that a positive feedback loop involving NFAT-induced TRPC6 expression contributes to the induction and/or maintenance of proteinuric disease.

The current findings add an additional downstream pathway secondary to calcineurin signaling in podocytes, in addition to the dephosphorylation of the actin-binding protein synaptopodin by calcineurin as we previously reported. Synaptopodin is vitally important in maintaining the podocyte actin cytoskeleton, and its dephosphorylation results in subsequent cathepsin L-mediated degradation, cytoskeletal disorganization, and proteinuria. Thus, our data contribute to a hypothetical mechanism by which AngII-induced and NFAT-mediated TRPC6 overexpression, as addressed in our experiments, fuel persistent calcineurin activation, leading to synaptopodin degradation as described previously, eventually perpetuating podocyte injury (Figure 8). For this hypothesis to be proven, it remains to be established whether Ca\(^{2+}\) influx through TRPC6 directly induces calcineurin-mediated dephosphorylation of synaptopodin.

In conclusion, we have demonstrated an AngII-induced, TRPC6-dependent, NFAT-mediated feedback mechanism driving TRPC6 transcription in podocytes. This finding underlines the crucial role of TRPC6 in the pathogenesis of podocyte injury and proteinuria.
